Magnesium Bisulfite and Sodium Bisulfite as Alternative Steeping Agents for Wet Milling

K. D. RAUSCH, S. K. SINGH, and S. R. ECKHOFF

Wet milling is the process by which whole corn is separated into fractions that are high in starch, protein, oil, and fiber. The initial stage of wet milling involves steeping the corn for 24-36 hr in a weak sulfuric acid solution created by adding small amounts of sulfur dioxide (1,000-2,000 ppm) to water. Steeping conditions bring to the germ to withstand the rigors of grinding and making it possible to separate the protein and starch of the corn endosperm.

The common methods for adding sulfur dioxide (SO₂) to the steep solution are to burn elemental sulfur or to bubble gaseous SO₂ directly into the steeping solution. Both methods require gaseous SO₂ to be absorbed by the steeping liquid, resulting in emissions of SO₃ into the atmosphere. Because of the volatility of SO₂, its reactivity, and its inherent pungent odor, there are related health and environmental concerns, not only for the milling facility, but also for the surrounding areas. The use of magnesium bisulfite (MBS) and sodium bisulfite (NaBS) steeping agents are attractive alternatives to SO₂ because they would not require any modifications to the milling process. They offer reduced SO₂ emissions because they bind SO₂ as a salt compound. These compounds are produced as solutions containing approximately 19-23% SO₂ by weight. They can be added to the steepwater without special absorption apparatus.

The objectives of this study were to investigate MBS and NaBS steeping agents as alternatives to conventional SO₂ and to determine any product-yield advantages of using these alternative compounds as steeping agents in the wet-milling process.

MATERIALS AND METHODS

Laboratory Wet-Milling Procedure

Laboratory-scale wet milling was performed in duplicate on corn samples using the procedure of Eckhoff et al (in press), which provides yields of germ, fiber, starch, gluten, steepwater, and gluten filtrate. Each 1,000-g corn sample was passed over a 12/64-in. (4.76-mm) round-hole sieve using a reciprocating Gamet shaker and hand-inspected to remove any moldy kernels before milling. All milling yields are presented on a dry solids basis.

Rheological data were collected for selected starch samples using a Brabender Viscoamylograph according to the procedures of Shuey and Tipples (1980). Thirty-five grams of starch, 3.6 g of sodium carboxymethyl cellulose and 450 ml of buffer were mixed together to determine: onset of gelatinization, peak viscosity, and initial viscosity after heating from 50 to 95°C; viscosity after 30 min at 95°C; initial viscosity after cooling to 50°C; and final cold paste viscosity after 30 min at 50°C. Amyllograph data were collected on starch from three hybrids (FR27 × FRMo17, FR618 × FR600, and FR1087 × LH123) steeped for 24 hr at 1,500 ppm concentrations of SO₂ and MBS solutions.

Effectiveness of Alternative Steeping Agents

A medium-hard hybrid of regular dent corn, FR618 × FR600, was wet-milled to investigate the effectiveness of MBS and NaBS solutions (Hydrite MBS 6310 and Hydrite NaBS solutions, respectively) obtained from the Hydrite Chemical Company, Waterloo, IA. The FR618 × FR600 hybrid had been dried at 80°C in a batch-type dryer from an initial moisture content of 26%, wet basis. This temperature is considered moderately high for drying corn and causes reduced starch and germ yields, increased fiber and gluten yields, and reduced starch quality when wet milled due to changes in steeping characteristics (Vojnovich et al 1975). Five combinations of steeping time (24 and 36 hr), steeping agent, and SO₂ concentration (1,000 and 2,000 ppm) were tested in duplicate (Table 1). Five additional runs of time and concentration combinations (SO₂ at 1,000 ppm for 18, 24, and 36 hr; MBS at 3,000 ppm for 36 hr; MBS at 1,000 ppm for 18 hr) were wet-milled for comparison. However, yield data for these tests are not presented in Table I because the runs were unreplicated. To investigate potential effects of hybrid differences, six additional, unreplicated runs were made. Hybrids (FR27 × FRMo17, FR618 × FR600, FR1087 × LH123) were steeped with 1,500 ppm of either SO₂ or MBS (SO₂ equivalent) for 24 hr.

RESULTS AND DISCUSSION

Effect of Steeping Agent on Product Yields

The average yields (Table I) from the duplicate milling runs of FR618 × FR600 hybrid corn dried at 80°C were representative of regular dent milling yields in industry (Knight 1969, Anderson and Watson 1982, May 1987). They were compared using the least significant difference method (a = 0.05). Yields from corn steeped with MBS and NaBS did not differ greatly from the yields of corn steeped using conventional SO₂. There were no significant differences for the fiber, gluten, filtrate, and total recovery yield means. Yields from all the unreplicated milling runs also showed no pronounced differences between steeping agents. Steepwater solids yields were somewhat higher for longer steeping times; the yield from the 36-hr 2,000-ppm MBS steep was significantly higher than that from the 24-hr 2,000-ppm MBS steep. This is attributed to increasing amounts of solubles leaching out of the corn into the steepwater as steeping time was lengthened.

The germ yield for corn steeped for 36 hr in 2,000 ppm SO₂ was similar to the MBS germ yield at the same conditions. It was significantly higher than all of the other treatments. However, the 36-hr 2,000-ppm MBS steep was statistically similar to the other MBS steeps and to the NaBS treatment. Since germ contain a large percentage of soluble material, longer steeping periods will leach more material from the germ (Fox and Eckhoff 1993). This removal of solubles causes the germ to have a lower specific gravity, making germ recovery more efficient.

Starch yield was significantly higher for the 36-hr 2,000-ppm SO₂ steep and significantly lower at the same conditions for the MBS steep. However, the other MBS steeping conditions were similar to the SO₂ steep, yielding contradictory results. In theory, the longer steeping times and higher SO₂ concentrations should result in higher starch yields. Comparison between Brabender amyllographs using SO₂ or MBS showed that the MBS had no significant effect on starch pasting and viscosity characteristics.

*Hydrate MBS 6310 magnesium bisulfite steeping agent.
**Hydrate NaBS sodium bisulfite solution steeping agent.
1 Least significant difference for each yield mean at α = 0.05.
2 Means followed by the same letter in the same row are not significantly different at α = 0.05, as determined by the least significant difference method. Yields are averages of duplicate milling runs.
3 Percentage total dry solids recovered in the milling process.

ACKNOWLEDGMENT
We wish to acknowledge the Hydrate Chemical Company for providing technical assistance and partial funding for this project.

LITERATURE CITED

CONCLUSIONS
MBS and NaBS steeping agents performed similarly to conventional SO₂-based on wet-milling yields and Brabender amylographs. The major advantage of MBS or NaBS may be in health and safety benefits brought about by changing occupational and environmental regulations.
